This is a PDF file of an unedited manuscript that has been accepted for publication. As a service to our customers we are providing this early version of the manuscript. The manuscript will undergo copyediting, typesetting, and review of the resulting proof before it is published in its final form. Please note that during the production process errors may be discovered which could affect the content, and all legal disclaimers that apply to the journal pertain.

## Highlights

- A multi-period hub set covering problem with flexible covering radius is presented.
- A dynamic model is proposed to solve the hub set covering problem with flexible covering radius.
- A modified genetic algorithm (GA) is proposed.
- A real world case study is presented for hub set covering problem with flexible covering radius.

# Multi-Period Hub Set Covering Problems with Flexible Radius: a Modified Genetic Solution 

First Author: Amir Ebrahimi zade,<br>Department of Industrial Engineering, Amir-Kabir University of Technology, Tehran, Iran, aebrahimyzade@yahoo.com Corresponding Author: Hasan Hossini-Nasab<br>Department of Industrial Engineering, Yazd University, Yazd, Iran, P.O.B 89195-741, Email: hhn@yazd.ac.ir Co-Author: Yahya zare mehrjerdí<br>Department of Industrial Engineering, Yazd University, Yazd, Iran, P.O.B 89195-741, Email: yazm2000@yahoo.com<br>Co-Author: Alireza Zahmatkesh Department of Industrial Engineering, Yazd<br>University, Yazd, Iran, P.O.B 89195-741, Email: alireza_121@yahoo.com

#### Abstract

Traditionally, in hub covering problems, it is assumed that the covering radius is an exogenous parameter which cannot be controlled by the decision maker. In many real-world cases, with a negligible increase in covering radius, considerable savings in hub establishment costs are possible. On the contrary, changes in problem parameters during the planning horizon cause the results of theoretical models to be impractical in real-world situations. This article proposes a mixed integer model for a multi-period single-allocation hub set covering problem in which the covering radius is a decision variable. The proposed model is validated through a real world case study. Also, due to the NP-Hardness of the problem a modified genetic algorithm (GA) is proposed for solving that. The proposed GA benefits from a dynamic stopping criteria and immigration operator. The performance of the proposed GA is compared with the original GA and imperialist competitive algorithm (ICA). Computational results corroborated efficiency of the proposed algorithm in achieving high-quality solutions in a reasonable time.

Keywords: Facility location, Dynamic hub set covering problem, Flexible covering radius, Mathematical modelling, Dynamic genetic algorithm, Immigration operator.

## 1- Introduction and literature review

The concept of hub nodes arises when there are many origin-destination (O/D) pairs in a transportation network to benefit from the economies of scale. Hubs are nodes in which the flow from various origins is gathered, and after reorganization, it is dispatched to the destinations. Hub location problems, initially introduced by O'Kelly [1], have many applications in cargo delivery systems, airline networks and telecommunication systems. O'Kelly proposed a quadratic model for hub median problem which was aimed at minimizing total flow costs [2]. Subsequent researches by Campbell [3], Ernst et al. [4], and O'Kelly et al. [5] proposed some linearized versions for the problem. Hub location problems are generally classified into three categories: hub center, hub median and hub covering problems. This article investigates on hub-covering problem. Readers can refer to the review papers by Alumur et al. [6], Farahani et al. [7], and Campbell and O'Kelly [8] for the other categories of hub location problem. Initially, Campbell proposed mathematical formulations for single and multiple-allocation versions of hub set covering problem (HSCP) and hub maximal covering problem (HMCP) [9]. He also proposed that an $\mathrm{O} / \mathrm{D}$ pair $i, j$, might be covered by hubs $k, l$ in three ways:

1. Total transport costs (time or distance) from origin $i$ to destination (via origin $i$ to hub $k$, hub $k$ to hub $l$, with a discount factor $\alpha ; 0 \leq \alpha \leq 1$, and hub $k$ to destination $j$ ) do not exceed a given covering radius.
2. Transport costs (time or distance) for each of the links in the path from origin $i$ to destination $j$ via hubs $k$ and $l$ do not exceed the covering radius.
3. Transport costs (time or distance) from origin $i$ to hub $k$ and hub $l$ to destination $j$ do not exceed the covering radius.

The existing models in the literature obey the above rules. They assume that the covering radius is an exogenous parameter, and the decision maker (DM) cannot control its size; however, in many real-world applications, covering radius is a decision variable. Sometimes it is possible to avoid establishing hub nodes with a slight increase in covering radii. For example, in a transportation network, equipping the existing facilities or establishing more spacious depots help increase the covering radius and consequently to serve farther customers. The capability of an airport to serve the flights has a direct proportion to the number of runways, facilities and infrastructure which can be increased when necessary. Also in a telecommunication system, the area covered by the radio waves depends on the strength of the transmitted waves, and with reinforcing the radiation, larger areas may be covered by the hub node. Accordingly, a larger covering radius, can prevent the superfluous costs of establishing new hubs. In order to capture this situation, two types of costs are considered for a hub node, fixed hub establishment and covering cost in which the latter is proportional to the selected covering radius for the hub node.

Facility location decisions are frequently long-term in nature. Facilities such as airports, dams, schools, hospitals, factories, distribution centers and retail outlets are often operated for decades. Consequently, there may be a considerable uncertainty regarding the relevant parameters in the location decision [10]. For example, as time goes on, the amount of supply and demand varies in origin and destination nodes. Moreover, transportation costs among nodes may vary due to the factors such as increasing the fuel cost, depreciation or using cheaper facilities in the fleet. Also time value of money, which is affected by the inflation and the interest rate, is very important in making managerial decisions [11]. These financial
factors may change during the planning horizon. Multi-period consideration of a problem enables the model to establish new facilities or close the existing ones periodically, which is proportional to the variation of the relevant parameters. From one point of view, dynamic facility location problems can be divided into two categories. The first category consists of problems in which the number of facilities is an exogenous parameter. In some cases like Zarandi et al. [12], the total number of facilities in the planning horizon is proposed by the DM and the number of facilities in each period is determined by the model. Also, in some cases like Drezner and Wesolowsky [13] and Wesolowsky and Truscott [14], the authors assumed a fixed number of facilities that can be relocated at the end of each period. The second category consists of problems in which the number of facilities is an endogenous parameter and is located such that the total costs are minimized. Contreras et al. [15] considered the un-capacitated dynamic hub location problem and proposed a mixed integer nonlinear programming model to solve that. While constructing hubs is costly, it is assumed that their closure is profitable because of the released resources. Also, Taghipourian et al. [16] studied a dynamic virtual hub location problem. The authors assumed that both closed and established hubs are costly. The hub covering problem investigated in this paper belongs to the second category. Table 1 addresses some of the major extensions to the hub covering problem. Referring to the table, existing formulations for hub covering problem are static, and the proposed dynamic model integrates previous viewpoints by considering both costs and benefits of the closed hubs. More realistic approach to the problem arises with more scrutiny on structure of the facilities. Facilities in a hub can be categorized into two types: static and movable facilities. Although, static facilities remain useless when a hub is closed, moving facilities can be transferred to newly developed hubs causing some savings. For example in a hub airport, some infrastructure facilities like building, watchtower and runways are static facilities and some like airport staff, office supplies or vehicles are moving facilities and their displacement causes savings in costs. It is assumed that the moving facilities released from the closed hubs are usable in only one of the newly established hubs in the same period. The saving associated to these movements is subtracted from the total costs of the period.

This article investigates on a multi-period HSCP with flexible covering radius. The model distinguishes between the costs and benefits of the closed hubs. Similar to the real-world situation, covering radius is assumed to be an endogenous parameter in which the amount is determined optimally. The proposed model helps the DM to design a transportation network by determining the established hubs, their covering radius and allocating ordinary nodes to the hubs. Also, multi period structure of the model enables the manager to involve changes of the problem parameters in the decision making process.

Table 1: Major contributions to the HSCP and HMCP

| Article | number of <br> periods | Major contribution | Solution approach |
| :---: | :---: | :---: | :---: |
| $[9]$ | single period | Introduction of HSCP and HMCP | Exact |
| $[17]$ | single period | New formulations for HSCP | Exact |
| $[18]$ | single period | New formulations for HSCP | Exact |

The rest of this paper is organized as follows. Section 2 is dedicated to the proposed solution approaches. Initially, Section 2.1 presents a mixed integer mathematical model, and due to the computational complexity of the problem, Section 2.2 proposes a dynamic genetic algorithm to solve it in a reasonable time. Computational results are presented in Section 3 and conclusions and some guidelines for further studies are presented in Section 4.

## 2. Multi period HSCP with flexible covering radius

It is assumed that $N=\{1,2, \ldots, n\}$ is the set of origin and destination nodes in the network. Each node is a potential location for establishing a hub. Let $i, j$ be the indices for origin and destination nodes respectively, $k, l$ be indices for the hubs and $t$ be the index for periods. Furthermore, it is supposed that the costs matrix is symmetric, this means that: $c_{i j}=c_{j i}$. The hub network is assumed to be a complete graph, and each O/D pair is connected through one or two intermediate hubs. Also, there is no limitation on the capacity of the hub nodes. Ordinary nodes may be connected to one hub (single allocation) or more than one hub (multiple allocations) in which the former is investigated here. Each hub contains two kinds of costs: fixed establishment and covering costs. Covering costs of a hub are proportional to its covering radius, and the covering radius of the hub equates to the farthest node covered by the hub. Between hubs transportation is discounted considering the use of special facilities $(0 \leq \alpha \leq 1)$. Given an O/D pair, $i, j$, transportation cost $\left(c_{t i j}^{k l}\right)$ in period $t$ equates to the sum of costs from $i$ to hub $k$, hub $k$ to hub $l$, considering the discount factor $\alpha$, and hub $l$ to $j$.

Whenever it happens, closed hubs are costly. However, the savings occur when there is a possibility to reuse the released movable facilities in newly established hubs. The following lemma is proposed to determine the number of possible movements in each period. It is assumed that after a hub is closed, movable facilities are transferred to one of the newly established hubs and are not capable of buffering for subsequent periods.

Lemma. Number of possible movements in each period equates to the minimum of total established hubs ( $\sum_{k} p_{t k}$ ) and total closed hubs in that period $\left(\sum_{k} q_{t k}\right)$.
Proof. Generally, in each period, there are three possible cases:
(a) The sum of established hubs is larger than the sum of closed hubs $\left(\sum_{k} p_{t k}>\sum_{k} q_{t k}\right)$. In this case, it is possible to reuse the released movable facilities from all of the closed hubs. Hence, number of movements will be $\sum_{k} q_{t k}$.
(b) Number of established hubs equals to the number of closed hubs $\left(\sum_{k} p_{t k}=\sum_{k} q_{t k}\right)$. In this case, movable facilities from each of closed facilities are allocated to one of the established facilities. Therefore, number of movements will be $\sum_{k} q_{t k}$ or $\sum_{k} p_{t k}$.
(c) Established hubs are less than closed hubs $\left(\sum_{k} p_{t k}<\sum_{k} q_{t k}\right)$. Despite extra supply, the demand is limiting, and it is possible to use moving facilities from $\sum_{k} p_{t k}$ of closed hubs in newly established ones.

Accordingly, the number of possible movements in each period equates to the minimum of total established hubs and total closed hubs.

This section contains two parts, each of which presents a solution approach to the addressed problem. The first part is devoted to the suggested mixed integer model and the second part proposes a dynamic GA for solving the problem.

### 2.1 Proposed formulation

Despite simpler formulations for HSCP in the literature, such as the one proposed by Ernst and Krishnamoorthy [4], the developed mixed integer model is based on the formulation by Campbell [9] for the sake of clarity. The set of model parameters is as follows:
$c_{t i j}^{k l} \quad$ Is the present value of total transportation cost from origin $i$ to destination $j$ via hubs $k$ and $l$ in period $t$.
$e c_{t k}$ Is the present value of fixed hub establishment cost in node $k$ in period $t$.
$f r_{t k}$ Is the present value of covering cost of a hub at node $k$ in period $t$.
$c c_{t k}$ Is the present value of hub closure costs at node $k$ in period $t$, including both static and movable facilities.
$m s_{t}$ Is the present value of the benefits from movable facilities in a closed hub in period $t$.
$d_{i k} \quad$ Is the Euclidean distance from node $i$ to hub $k$.
$M$ Is a big number.
The set of decision variables in the model is as follows:
$x_{t i j}^{k l} \quad$ A binary decision variable which is 1 if nodes $i$ and $j$ are connected via hubs $k$ and $l$ in period $t$ and otherwise equals 0 .
$y_{t i k}$ A binary variable which is 1 if node $i$ is connected to hub $k$ in period $t$ and otherwise it is 0.
$r_{t k}$ Is the covering radius of hub $k$ in period $t$.
$p_{t k}$ Is a binary variable which is 1 if a new hub is established at node $k$ in period $t$ and otherwise equals 0 .
$q_{t k}$ Is a binary variable which is 1 if the existing hub in node $k$ is closed in period $t$ and otherwise equals 0 .
$z_{t} \quad$ Is the minimum of $\sum_{k} p_{t k}$ and $\sum_{k} q_{t k}$.
Considering the above explanations, the proposed mathematical model is as follows.
$\operatorname{Min} \sum_{t} \sum_{i} \sum_{k} \sum_{l} \sum_{j} c_{t i j}^{k l} x_{t i j}^{k l}+\sum_{t} \sum_{k} e c_{t k} p_{t k}+\sum_{t} \sum_{k} f r_{t k} r_{t k}+\sum_{t} \sum_{k} c c_{t k} q_{t k}-\sum_{t} m s_{t} z_{t}$
$\sum_{k} \sum_{l} x_{t i j}^{k l}=1 \quad \forall i, j, t$
$2 x_{t i j}^{k l} \leq y_{t j l}+y_{t i k} \quad \forall t, i, k, l, j$
$y_{t i k} \leq y_{t k k} \quad \forall t, i, k$
$\sum_{k} y_{t i k}=1 \quad \forall t, i$
$r_{t k} \geq d_{i k} y_{i k} \quad \forall t, i, k$
$p_{t k}-q_{t k}=y_{t k k}-y_{t-1 k k} \quad \forall k, t>1$
$z_{t}=\min \left(\sum_{k} p_{t k}, \sum_{k} q_{t k}\right) \quad \forall t$
$x_{t i j}^{k l}, y_{t i k}, p_{t k}, q_{t k} \in\{0,1\}, r_{t k} \geq 0, z_{t} \geq 0 \&$ integer
Expression (1) is the objective function of the proposed model which is aimed at minimizing the total costs. The first part of the objective function considers transportation costs from origin $i$ to destination $j$ via hubs $k$ and $l$. The second part is dedicated to the hub establishment costs. Covering cost of each hub in each period is the third part of the objective function. Costs associated with the closed hubs in each period are the fourth part, and the benefits from movable facilities are calculated in the fifth part. Constraints (2) guarantee that each O/D pair is connected through one or two hubs. Constraints (3) ensure that the path from $i$ to $j$ via hubs $k$ and $l$ is established if both $i$ and $j$ are, respectively, connected to hubs $k$ and $l$. Constraints (4) ensure that in each period, ordinary node $i$ may be connected to $k$ if it is set as a hub. Constraints (5) ensure that each node allocates to only one hub (single-allocation constraint). Covering radius equates to the distance between the hub and farthest ordinary node allocated to it, which is calculated in (6). According to (7), for a given node $k$ in period $t$ when a hub is newly established, binary variable $p_{t k}$ equals 1 and binary variable $q_{t k}$ equals 0 and when the existing hub in a node is closed, $q_{t k}$ equals 1 and $p_{t k}$ equals 0 . Otherwise, both variables will be zero. Constraint (8) expresses the proposed lemma, upon which the number of possible movements in each period equates to the minimum number of
established and closed hubs. Expression (9) specifies $x_{t i j}^{k l}, y_{t i k}, p_{t k}$ and $q_{t k}$ as binary variables and $r_{t k}, z_{t}$ as nonnegative variables.

The following set of linear constraints may be substituted with nonlinear equation (8). Referring to (10), $v_{t}$ is the subtraction of $\sum_{k} q_{t k}$ from $\sum_{k} p_{t k}$. Using constraints (11) and (12) if $v_{t}$ is negative, binary variable $w_{t}$ will be 1 , otherwise it is 0 . Constraints (13) and (14) provide an upper bound for $v_{t}^{\prime}$. Accordingly, if $w_{t}=1$, then $v_{t}^{\prime} \leq v_{t}$ and if $w_{t}=0$, then $v_{t}^{\prime} \leq 0$. Therefore, considering equation (15), the upper bound of $z_{t}$ is the minimum of $\sum_{k} q_{t k}$ and $\sum_{k} p_{t k}$. However, considering the utility of larger values of $z_{t}$ in the objective function, it will attain the upper bound.
$v_{t}=\sum_{k} p_{t k}-\sum_{k} q_{t k} \quad \forall t$
$v_{t} \geq-M w_{t} \quad \forall t$
$v_{t}<M\left(1-w_{t}\right) \quad \forall t$
$v_{t}^{\prime}-M\left(1-w_{t}\right) \leq v_{t} \quad \forall t$
$v_{t}^{\prime} \leq M w_{t} \quad \forall t$
$z_{t}=v_{t}^{\prime}+\sum_{k} p_{t k}-v_{t} \quad \forall t$
$w_{t} \in\{0,1\}, v_{t}, v_{t}^{\prime} \geq 0$

### 2.2 Proposed genetic algorithm

To proof NP-hardness of a given problem, it is a common practice to show that it is at least as hard as another proven NP-hard problem [31]. Kara and Tansel proved the NP-hardness of HSCP [17]. On the other hand, the problem investigated in this article may be simplified to the classic HSCP when the number of periods in the planning horizon is limited to one and the covering radius has a predetermined level. Therefore the problem discussed here, will be NP-Hard as well. The complexity of the problem leads to a high computational time for even medium and small-sized instances. To obtain suitable solutions in a reasonable computational time, a genetic algorithm (GA) is proposed for the investigated problem. GA is a meta-heuristic algorithm, based on Darwinians theory of evolution, first introduced by Holland [32]. GA transmits a set of solutions for consecutive iterations, namely population, and in each iteration, some new individuals are added to the population and some individuals with lower utility will be eliminated. This goes on until a predetermined stopping criterion is met.

GA has properties such as the chromosomes structure, initial population, selection strategies, genetic operators and stopping criteria, which determine the performance of the proposed algorithm. The following subsections describe each of these features for the proposed GA.

### 2.2.1 Chromosome structure

One of the most important specifications of the GA, with a noticeable effect on the efficiency of algorithm, is the chromosome structure. The proposed structure, presented in Figure 1, must capture all the features of the problem. In the first stratum of the proposed structure, each allele represents a node and its content determines the hub to which it is assigned, accordingly, self-assigned nodes are interpreted as hubs. Length of a chromosome equates to the number of nodes multiplied by the number of periods. Considering the difficulty of implementing the GA operators on the first stratum, the second stratum is introduced in which the hub nodes are appointed.

| 4 | 3 | $\mathbf{3}$ | $\mathbf{4}$ | 3 | 2 | $\mathbf{2}$ | $\mathbf{5}$ | $\mathbf{2}$ | $\mathbf{5}$ | $\mathbf{1}$ | 1 | $\mathbf{3}$ | 1 | 1 |
| :--- | :--- | :--- | :--- | :--- | :--- | :--- | :--- | :--- | :--- | :--- | :--- | :--- | :--- | :--- |
| 0 | 0 | 1 | 1 | 0 | 0 | 1 | 0 | 0 | $\mathbf{1}$ | 1 | 0 | 1 | 0 | 0 |
| period 1 | period 2 | period 3 |  |  |  |  |  |  |  |  |  |  |  |  |

Figure1. The chromosome structure

### 2.2.2 Initial population

GA is a population-based algorithm and permanently transmits a set of individuals to consecutive iterations. First, it is necessary to generate a set of solutions as initial population. To emphasize the importance of the population size, it is noticeable that extra-large size of the initial population results in trashy increase of computational time and small size of the population will cause the algorithm not achieving to optimal solution. Based on the parameters tuning results, initial population consists of 200 individuals. To create the population, some of the nodes are selected as hubs and the others are allocated to the nearest hubs.

### 2.2.3 Selection strategies

There are different methods to select parents for implementing crossover and mutation. Roulette wheel method, first introduced by Goldberg [33], is applied here. In this approach, after sorting all population members based on their fitness, each one will be allocated a selection probability proportional to its rank. In this situation, all the members of the population have the chance to be selected, although the chromosome with a better fitness is more likely to be chosen.

### 2.2.4 Genetic operators

Premature convergence to a non-optimal solution is probably the most serious problem encountered in GA [34]. The operators in GA are tools to avoid the premature convergence. Reproduction causes to add new individuals to the population which the characteristics are their parent's patrimony. This phenomenon is presented in crossover operator. Scarcely, and due to disorder in structure, some of the individuals have salient differences with the others. Similar to the illustrious role of mutation in the human evolution, this operator also is very important for the GA in salvation from local optima. A phenomenon that many human societies are faced with, is the immigration. Inspired from the real world populations, the proposed algorithm applies the immigration as a GA operator.

Crossover is the basic operator of GA for combining two chromosomes [35]. There are multiple methods for implementing crossover. Here a modified version of single-point crossover is proposed. It is noteworthy that the investigated problem is a multi-period one; therefore, single-point crossover might not be suitable. For more efficiency a $k$-point crossover is proposed, where $k$ is the number of periods. Each cut point is located randomly within one of the periods. Crossover on the first stratum might result in an infeasible solution, therefore the second stratum of the chromosome is used to do a crossover. Crossover on the second stratum of a hypothetical chromosome is presented in Figure 2.

Figure2. Crossover on the second stratum of a chromosome with four periods
Mutation is the second operator of GA. When the solution remains unchanged for consecutive iterations, the algorithm might be trapped in local optima. This operator prevents the algorithm from trapping in local optima by the exploring solution space [36]. The proposed mutation operator is conducted on the second stratum of the chromosome. To mutate a chromosome, some of the genes are selected randomly. If the selected node is a hub, it is changed to an ordinary node. Otherwise it is altered to a hub. Figure 3 shows mutation on a hypothetical chromosome with three periods in which 4 nodes are mutated. One of the possible occurrences is to make a period without any hubs, like the third period in Figure 3. In this case, the same number of the genes are selected randomly to be hubs.

Figure3. The mutation operator
Although increasing the number of changes in a selected chromosome for mutation causes the increment of computational time, more changes provide better search in solution space. Proposed dynamic mutation operator increases the number of changes in a selected chromosome for mutation along with increasing the number of iterative solutions. The number of genes that are remodeled in a mutant ( nm ) is presented in (17).

$$
n m= \begin{cases}\left\lceil\frac{\text { nnode }}{5}\right\rceil & \text { if } \mathrm{IS}<\frac{\max \text { it }}{3} \\ \left\lceil\frac{\text { nnode }}{3}\right\rceil & \text { if } \mathrm{IS}<\frac{\max \text { it }}{3}  \tag{17}\\ \left\lceil\frac{\text { nnode }}{2}\right\rceil & \text { if } \mathrm{IS}>\frac{\max \text { it }}{2}\end{cases}
$$

Where $n m$ is the number of remodeled genes in a chromosome, nnode is the number of origins and destinations, $I S$ is the number of the iterative solutions in which the best solution found by the algorithm remains unchanged, and maxit is the maximum number of iterations.

The third operator introduced here is called immigration. It is assumed that there are some immigrants to the society in each period. In real-world situation, alongside with the economic and scientific growth of a society, general tendency of the people from other populations increasses to immigrate to the society, similarly the designed dynamic operator increases immigration rate with increasing the probability of achieving the global optima, which the sign is a fixed solution for consecutive iterations. Increasing the immigration rate, as well as the mutation rate, increases the algorithm's capability to avoid local optima. Similar to the initial population, immigrants are created randomly and the rate of immigration is presented in (18).
$I M_{p}=\frac{I S}{n_{p o p}}$
Where $I S$ is the number of consecutive iterations in which the best solution remains unchanged, $n_{P O P}$ is the number of individuals in the population and $I M_{p}$ is the immigration rate.

### 2.2.5 Stopping criteria

Various criteria have been introduced to stop the GA computational processes. The maximum number of iterations is the one most widely used as the stopping criteria. In some cases, the algorithm attains the optimum solution in primal iterations and remains unchanged until the last iteration. There are two possibilities: first, the algorithm is trapped in a locally optimal solution. In this case, as described in Section 2.2.4, the designed algorithm tries to escape the trap by increasing the severity of search in solution space with the aid of intensifying the number of permutations in a mutant and increasing the immigration rate. Second, the possibility is that the algorithm has reached optimum solution; in this case, it is ideal to stop the algorithm immediately. To reduce the computational time in the latter case, another stopping criterion is utilized alongside with the maximum number of iterations. Provided that the best solution remains unchanged for $\frac{\text { maximum iterations }}{2}$, the algorithm will be terminated.
To aggregate the above explanations, the flowchart of the proposed GA is presented in Figure 4.

Figure 4. Flow chart of the proposed GA

## 3. Numerical experiments

In this section, numerical examples are conducted to evaluate the developed mathematical model and the proposed GA. To discuss the main outcomes of the mathematical model, a real world case study is presented in Section 3.1. Also, to analyze efficiency of the proposed GA, the results are compared with the original GA and ICA. The proposed GA differs from the original GA in the immigration operator,
dynamic mutation, and the stopping criteria. To analyze the effects of these features, the results of proposed GA are compared with the results of the original GA. Parameters calibration and the obtained results are presented in Section 3.2, and the computational results are provided in Section 3.3.

Proposed GA, original GA and ICA are coded and implemented in MATLAB R2011b running on a system with 4 GB of RAM and core i5 CPU. Furthermore, the optimal solutions are obtained by GAMS 22.2 using CPLEX solver.

### 3.1 Case study

It is estimated that $\$ 40-100$ billion is paid annually to keep Iranians, supplied with cheap energy, water, fuel, and basic food [37]. Thereupon the government has devised a multistep plan, namely the targeted subsidiary plan, to cut the subsidies. During the first phase of the plan in 2010, fuel prices had a $400 \%$ enhancement, upon which a noticeable increase in the transportation costs happened.

The investigated case is a cargo delivery firm which serves in 11 provinces. The problem is to design a hub network under the described price increases. Initially the plan was implemented in 5 pilot provinces and after 6 months, it was held nationwide. The first period $\left(\mathrm{P}_{1}\right)$ refers to the full subsidy prices before starting the plan. Intensity of transportation (tons per day) and unit transportation cost of the first period, are presented in the upper and lower diagonal of Table 2 respectively. During the second period $\left(\mathrm{P}_{2}\right)$, subsidies are cut in 5 provinces, highlighted provinces in Figure 5 (b), and finally the third period $\left(\mathrm{P}_{3}\right)$ represents free prices. Transportation costs for the second and third period are provided in the upper and lower diagonal of Table 3 respectively. Referring to the World Bank statistics, inflation rate has moved from $10.1 \%$ in the first period to $20.6 \%$ in the second and third period [38], upon which the related costs are inflated in Table 4. Also due to the possibility of selling surplus land and reusing movable facilities, it is assumed that in a closed hub, $60 \%$ of the costs are retrievable (closure benefits). The discount factor ( $\alpha$ ) and covering cost $(f r)$ are assumed to be 0.4 and 10 dollars per kilometer respectively.

GAMS 22.2 is applied to solve the problem. Table 5 presents the established hubs, their covering radius and the ordinary nodes allocated to each one. The total costs of the designed network is $\$ 6774117$ from which $\$ 4892841$ is the total transportation costs and $\$ 1820576$ is the hub established cost. Also the designed network is represented in Figure 5. Considering the dynamic nature of the problem, covering radius of a hub might be changed in each period. According to Table 5, the covering radius of Shiraz is 1100 kilometers in the first period (the distance between Shiraz and Zahedan) while its covering radius in the second and third period is 659 kilometers (the distance between Shiraz and Ahwaz).

### 3.2 Parameters setting

Parameter calibration plays an important role in the efficiency of metaheuristic algorithms. In this article Taguchi method is applied for parameters tuning. To reduce the number of experiments, this method proposes a fractional factorial experiment instead of full factorial experiments. Taguchi method divides the factors in to signal (or controllable) and noise factors. The method tries to minimize the effect of noise and determines the optimal level of the signal factors [39]. For a comprehensive study on the Taguchi method, the readers are referred to works of Peace [40] and Taguchi et al. [41].

Based upon the previous experiments, each parameter (or factor) is assigned three levels. Table 6 presents the parameters, their abbreviations, and the intended levels. The parameters are analyzed with an $\mathrm{L}_{9}$ design and each experiment is run 5 times. Considering the minimization nature of the objective function, a lower response level is more desirable. Accordingly the signal-to-noise ( $\mathrm{S} / \mathrm{N}$ ) ratio is calculated as follows.
$S / N=-10 \log \left(\frac{1}{n} \sum_{i=1}^{n} y_{i}^{2}\right)$
Where $y_{i}$ is the response in the $i$ th replication and $n$ is the number of replications in experiments. $\mathrm{L}_{9}$ orthogonal array and the obtained responses are provided in Tables $7-9$. Mean $\mathrm{S} / \mathrm{N}$ ratios for each algorithm are presented in Figure 6. Notably, a larger value of the $\mathrm{S} / \mathrm{N}$ ratio is more desirable. Referring to Figure 5, in the proposed GA, parameters Maxit, $\mathrm{N}_{\mathrm{P}}, \mathrm{P}_{\mathrm{m}}$, and $\mathrm{P}_{\mathrm{c}}$ should be set at levels 3, 2, 1, and 3 respectively. Selected parameters for each of the algorithms are shown in Table 10.

| Algorithm | Factor levels |  |  |  |
| :---: | :---: | :---: | :---: | :---: |
|  | Parameters | 1 | 2 | 3 |
| Proposed GA and | Maximum number of iterations (Maxit) | 150 | 200 | 250 |
| original GA | Population size $\left(\mathrm{N}_{\mathrm{P}}\right)$ | 100 | 200 | 300 |
|  | Mutation rate $\left(\mathrm{P}_{\mathrm{m}}\right)$ | 0.10 | 0.15 | 0.20 |
|  | Crossover rate $\left(\mathrm{P}_{\mathrm{c}}\right)$ | 0.70 | 0.80 | 0.85 |
| ICA | Number of imperialists $\left(\mathrm{N}_{\mathrm{I}}\right)$ | 5 | 9 | 13 |
|  | Number of colonies $\left(\mathrm{N}_{\mathrm{C}}\right)$ | 100 | 150 | 200 |
|  | Revolution rate $\left(\mathrm{P}_{\mathrm{R}}\right)$ | 0.05 | 0.10 | 0.15 |
|  | Assimilation rate $\left(\mathrm{P}_{\mathrm{A}}\right)$ | 0.70 | 0.75 | 0.80 |

Figure 6. Mean S/N ratios for the proposed GA (a), original GA (b), and ICA (c)

### 3.3 Computational results

The results of proposed GA are compared with the results of the mathematical model, original GA, and ICA. For this purpose, some numerical examples are solved. In the designed problems, fixed hub establishment cost, ranges uniformly in [7000, 12000] and the closure benefits have a uniform distribution in $[4000,7000]$. Costs and benefits might change periodically with rate $1+\alpha$, in which $\alpha$ has a uniform distribution in $[-0.05,0.15]$. Closure costs are uniformly distributed in [1000, 4000]. Covering costs are proportionate to the covering radius. Distances have uniform distribution in [33, 99], and the covering cost equates to the distance multiplied by 10 . Closure costs change periodically with the rate $1+\gamma$, in which $\gamma$ is uniformly distributed in $[-0.2,0.8]$. Numerical experiments have $5,10,15,20,25,30$, $40,60,80$, and 100 nodes. The discount factor ( $\alpha$ ) equates to $0.3,0.6$ and the number of periods ( $(\mathrm{t}$ ) is 2,3 and 4. In Tables 11 and 12, each sample problem is denoted as " $a-b-c$ " where " $a$ " is the number of periods, "b" is the number of nodes, and "c" is the discount factor.

Objective value and computational time for the proposed mixed integer model and the GA are presented in Table 11. Also, the table determines the total established hubs (TEH), total closed hubs (TCH) and
number of facility movements (NM) during the planning horizon. As shown in Table11, in the experiments with 5 nodes, mathematical model performs faster than the proposed GA; however, by increasing the problem size, its computational time has an exponential growth. Figure 7 compares the growth in computational time of the mathematical model with the proposed GA. It is obvious from the table that along with increasing number of periods $(t)$, computational time increases in both GAMS and GA solutions. Referring to Table 11, discount factor $\alpha$ does not have a meaningful effect on the computational time, whereas the objective value increases with increasing the discount factor in most cases. Also, according to Table 12 the proposed GA is superior to both the original GA and the ICA in all of the experiments.

Furthermore, the proposed GA provides high-quality solutions. For problems in which the optimal solution was found in a reasonable time, the proposed GA attains the optimum solution in all cases (Table 11). The proposed GA is compared with the original GA and ICA in Table 12. The relative gap between the optimal solutions and the solutions obtained by the original GA and ICA is presented in Table 12. For instances with 25 nodes and less, the calculations are:

$$
\begin{equation*}
\frac{O b j_{\text {heuristic }}-O b j_{\text {optimal solution }}}{O b j_{\text {optimal solution }}} \times 100 \tag{20}
\end{equation*}
$$

And for the problems with more than 30 nodes (30, 40, 60, 80 and 100 ); it is calculated as bellow.

$$
\begin{equation*}
\frac{O b j_{\text {heuristic }}-O b j_{\text {proposed GA }}}{O b j_{\text {proposed GA }}} \times 100 \tag{21}
\end{equation*}
$$

The results confirm the superiority of the proposed GA to the ICA and to the original GA in all instances with regard to the relative gap.

In addition to the computational time, the number of function evaluations (NFE) is a well-known performance indicator for the algorithms. Unlike the original GA, the proposed GA is a dynamic algorithm in which the number of iterations and the number of evaluated chromosomes are not predetermined. The original GA evaluates the fitness function 51300 times in each experiment; however, computational results in Table 12 indicate a smaller NFE (with the average 30448) for the proposed GA in all of the instances.

Figure 7. Growth of computational time

Table 11: GAMS output versus the proposed GA

| Problem | GAMS |  |  |  |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |

## 4. Conclusion

The article proposes a multi-period HSCP with flexible covering radius. There are many real-world applications such as telecommunication network or cargo delivery systems in which the covering radius is a flexible parameter rather than a fixed one. The proposed model assumes a fixed hub establishment and variable covering cost in which the latter is proportional to the area covered by the hub. Furthermore, to exert the changes in problem parameters during the planning horizon, a dynamic model is proposed. Facilities are divided into movable and static, and the savings from released movable facilities as well as the closure costs for static ones are taken in to account. Considering the computational complexity of the problem, an effective GA is proposed to solve it. The proposed GA benefits from dynamic migration and mutation operators which helped the algorithm to avoid trapping in local optima. The algorithm is compared with the original GA and ICA. The results showed that the proposed GA outperforms ICA and
original GA in the quality of the obtained solutions. Also the proposed GA is superior to the applied optimization toolbox (GAMS) and original GA in computational time.

The dynamic model proposed here, assumes that the savings resulting from movable facilities are the same for all hubs in a period. An interesting further research direction is to assume that the debated savings are variable for different hubs due to their sizes and other features.
